Abstract
Angular coronal deformities around the knee are common in pediatric orthopedic practice, surgical treatment is needed when the deformity persists or progress after correction of underlying biochemical abnormalities. Corrective osteotomy unlike in adults is not satisfactory in growing children due to potential complications, therefore growth modulation surgeries are preferred in children. Staples and screw hemiepiphysiodesis are associated with permanent damage to the physis and growth disturbances. The titanium-based figure of 8 plates were introduced to overcome growth plate injuries and growth disturbances in growth modulation surgeries. We aim to evaluate the functional results of 8 plates in growth modulation in angular knee deformities.

In this study, we had 25 knees in 16 patients with coronal angular deformities, with Genu Valgum in 18 knees (6 B/L) and Genu Varum in 7 cases (3 B/L). The mean deformities were Genu valgum of 25° and Genu Varum of 15°, with altered gait on ambulation. After surgery with 8 plates, mean correction of Genu Valgum was 13° and Genu Varum was 15°. The rate of deformity correction was 2.5° in both physeal surgery, 2° in distal femur physeal surgery and 1.5° in proximal tibial physeal surgery. There was no implant loosening, breakage, growth arrest, and physeal bar formation. Three patients had a superficial incisional infection which responded to the oral antibiotics. Two patients developed LLD of less than 2 cm without evidence of physeal injury or bar formation.

Growth modulation with the figure of 8 plates is a reliable and reproducible method of correction of angular deformities around the knee in skeletally immature patients with good functional outcome.

Keywords: coronal angular deformities, genu valgum, genu varum
INTRODUCTION

Angular knee deformities in children are commonly seen in pediatric orthopedic practice and usually resolve on their own in early childhood. However, sometimes these angular deformities result in gait abnormality, knee pain, patellofemoral instability, joint laxity and early joint degeneration due to eccentric joint loading [1,2]. After correcting underlying medical causes (biochemical abnormalities, rickets, etc), persisting angular deformities are corrected surgically, the corrective osteotomy has been widely practiced. The corrective osteotomy with the potential limitations like long duration of limb immobilization, non-weight bearing, discomfort due to plaster of Paris and unpredictable nature of deformity correction in children, paved the way for the growth modulation surgeries for coronal angular deformities around the knees [3,4]. The initial success of growth modulation with staples has diminished due to implant migration, implant failure, premature physeal closure and physeal damage [5-9]. Likewise, the transphyseal screw fixation for growth modulation doesn’t result in a predictable degree of correction with the possibility of the early physeal closure and subsequent development of reverse deformity [10].

Introduction of the figure of 8 plates has overcome the complication of growth modulation surgeries as it does not violate the periosteum and the perichondral ring around the physes, no permanent physeal damage, predictable degree of correction of deformity, no need of prolonged immobilization and non-weight bearing [11-14]. The aim of our study is, to evaluate the functional outcome of the patients treated with the figure of 8 plates for growth modulation in angular deformities of the knees regarding the of the degree of correction, the rate of correction, rehabilitation compliance and continuing routine activities of daily life like schooling and playful activities [15].

MATERIALS AND METHODS

The Children of either sex, with angular deformities around the knee, younger than 12 years of age treated with the figure of 8 plates for growth modulation surgeries were enrolled in this study. Children with deformity due to secondary causes like trauma, malunion, infection around physes (post osteomyelitis and septic arthritis), and skeletal dysplasias were excluded from the study. Our study involved 25 knees, with genu valgum in 18 knees (6 bilateral cases) and genu varum in 7 knees (3 bilateral cases). All the patients were evaluated preoperatively and postoperatively for gait abnormality, foot progression angle, stature, limb length discrepancy, intermalleolar and intercondylar distances (Fig. 1). Preoperative standing weight-bearing X-ray of both lower limbs was taken for calculation deformity (Fig. 2).

RESULTS

There were 25 knees in 16 patients, 11 male and 5 female patients, included in this study. Nine patients had bilateral knee deformity (6 B/L G. valgum and 3 B/L G. varum). Unilateral Genu valgum deformity in 6 knees and Genu varum in 1 knee. Mean Genu valgum deformity was 25° (range 17°-35°) and mean Genu varum was 15° (range 10°-30°). Post-operative improvement in Genu valgum was 25° to 12° and for Genu varum it improved from 15° to 0°. Post-operatively gait improved to normal and mean improvement in Mechanical tibio-femoral axis was 10 ± 4° in single physeal surgery versus 17 ± 5° in two physeal (both distal femur and proximal tibia) surgeries. There was Improvement of about 8 ± 5° in proximal tibial physeal surgery versus 10 ± 4° in distal femoral physeal surgery. On an average, the correction rate was
ANGULAR DEFORMITIES AROUND THE KNEE

Angular deformities around the knee are one of the common conditions observed in pediatric orthopedic practice, however, all of these deformities don’t merit surgery. Most of the cases are just borderline for which no surgical treatment is required. The reassurance and physiotherapy to elevate the early fatigability of child and anxiety of parents is all that is needed. Severe deformities in early childhood due to metabolic causes, respond well to biochemical metabolic corrections over a period of time. Surgery is reserved for residual deformities after correcting the biochemical abnormalities if present and severe deformities with gait abnormality. Surgical treatment, aimed at correction of the deformity and simultaneously allowing the patient to continue social activities and schooling, cannot be achieved with osteotomy and immobilization of the limb in plaster. Growth modulation surgery involves correction over a period of time and simultaneously allowing social activities of the child is valuable in correcting these deformities. The figure of 8 plates is accepted and simultaneously allowing social activities of the child is valuable in achieving growth modulation correction in deformed knees. Correction of simultaneous bilateral knee deformity is possible with this method of growth modulation surgeries and allowing satisfactory results and targeted correction without violating the physeal structure.

Extraperiosteal 8 plate act as a tension band for the growing physis, which act as the forces for correction of angular deformities in growing children [11,12]. Patients with pathological causes like dysplasia and syndromic association are treated earlier than patients of idiopathic and biochemical abnormalities corrected by medical management. Timely correction of angular deformities around the knee prevents fixed secondary compensatory deformities around hip, and feet [16].

We didn’t come across any premature physeal closure or bar formation, as also supported by the earlier studies using 8 plates for growth modulation surgeries [12,17,18]. As compared to staples, the figure of 8 plates is less damaging to the physis by application, removal, and mechanism of Tension band effect extra periosteally at physis [19]. The nonlocking nature of screws in 8 plates have a divergence play of about 30 degrees between the screws as compared with staples, thus resulting in less physeal damage. Due to the above-mentioned property of 8 plate, it can be left in situ for more than 24 months for deformity correction, thus achieves an effective correction of about 95% of angular deformities around knee [16,19]. There was no case of implant loosening or displacement of implant in our series, unlike staples in which these complication get magnified in patients of less than 8 years of age as reported by earlier series in a comparison study of 8 plate and staples for correction of angular deformities around knee, this study also demonstrated accelerated rate of correction with 8 plates than staples [16]. The rate of deformity correction is more in children with age less than 10 years (2.1°/month) as compared to children more than 10 years of age with only 0.6°/month correction rate [20,21]. The Rate of deformity correction is even less in children with syndromic/ dysplasias as compared to idiopathic cases [16].

Mean correction of mechanical axis after 8 plates in isolated proximal tibial physeal surgery were 1.5°/month and distal femur physeal surgery was 2°/month and for the dual physeal surgery (both distal femur and proximal tibia) was 2.5°/month approximately, this is in accordance with the published literature (Fig. 4) [17,20]. And the degree of correction and results are consistent with earlier reported series [9,16,22].

The figure of 8 plates is a titanium metallic plate with titanium non-locking screws, a costly method than stapling, however, the extraperiosteal and accurate placement of screws is possible which is superior to the staple placement. Even after 8 plate removal, there were some growth disturbances observed in this study, which needs further research for the mechanism and prevention of growth disturbances, so that the chances of the growth disturbances can be predicted and corrective measures can be formulated for the same. In our study owing to small no. of cases (16 patients) with 25 knees, we cannot generalize the limited complication rate and the phenomenon of growth disturbances after 8 plate removal.
CONCLUSION

Growth modulation with the figure of 8 plates is, simple reliable, reproducible and have fewer complications than stapling and other surgical methods of angular coronal deformity correction in growing children, with no need of prolonged immobilisation and non-weight bearing.
